ABSTRACT

Rates and patterns of synonymous and nonsynonymous substitutions have important implications for the origin and maintenance of mammalian isochores and the effectiveness of selection at synonymous sites. Previous studies of mammalian nuclear genes largely employed approximate methods to estimate rates of nonsynonymous and synonymous substitutions. Because these methods did not account for major features of DNA sequence evolution such as transition/transversion rate bias and unequal codon usage, they might not have produced reliable results. To evaluate the impact of the estimation method, we analyzed a sample of 82 nuclear genes from the mammalian orders Artiodactyla, Primates, and Rodentia using both approximate and maximum-likelihood methods. Maximum-likelihood analysis indicated that synonymous substitution rates were positively correlated with GC content at the third codon positions, but independent of nonsynonymous substitution rates. Approximate methods, however, indicated that synonymous substitution rates were independent of GC content at the third codon positions, but were positively correlated with nonsynonymous rates. Failure to properly account for transition/transversion rate bias and unequal codon usage appears to have caused substantial biases in approximate estimates of substitution rates.

T is well known that synonymous substitution rates 👃 vary among mammalian nuclear genes (Bernardi et al. 1993; Wolfe and Sharp 1993; Mouchiroud et al. 1995). Investigations of this variation, however, are complicated by nonuniform patterns of base composition among different regions of the mammalian genome. Mammalian genomes are structured into large regions (>300 kb) of distinct and homogeneous nucleotide composition known as isochores (Bernardi 1993). Both natural selection (BERNARDI and BERNARDI 1986; Gautier and Mouchiroud 1998; Eyre-Walker 1999) and mutation pressure (FILIPSKI 1988; WOLFE and SHARP 1993; FRANCINO and OCHMAN 1999) have been hypothesized as important mechanisms for the origin and maintenance of isochores. Consequently, the relationship between synonymous rate and nucleotide composition has been the subject of debate (e.g., BERNARDI et al. 1993).

Most studies report that genes with high GC content have lower silent substitution rates than genes with intermediate GC content (FILIPSKI 1988; TICHER and GRAUR 1989; WOLFE et al. 1989; WOLFE and SHARP 1993; EYRE-WALKER 1994). However, others (MIYATA et al. 1982; BERNARDI et al. 1993; MATASSI et al. 1999) concluded that synonymous substitution rates are independent of

nucleotide composition. Recently, SMITH and HURST (1999) analyzed a large sample of mouse and rat genes and found a significant positive correlation when maximum likelihood (ML) was used and no correlation when approximate methods were used. SMITH and HURST (1999) suggested that this methodological bias hindered further investigation of the relationship between synonymous rate variation and GC content.

A number of authors have reported that synonymous and nonsynonymous rates are positively correlated in mammalian genes (Graur 1985; Li et al. 1985; Wolfe and Sharp 1993; Mouchiroud et al. 1995; Ohta and INA 1995; MAKALOWSKI and BOGUSKI 1998; SMITH and HURST 1999). This observation, taken together with patterns of within-gene rate variation, recently led ALVAREZ-Valin et al. (1998) to hypothesize that selection is acting to enhance translational accuracy in mammals. However, this interpretation of the correlation between synonymous and nonsynonymous substitution rates also is controversial (Eyre-Walker 1991; Smith and Hurst 1999). Smith and Hurst (1999) hypothesized that selection for RNA structure and tandem substitutions, rather than translational accuracy, dominates the evolution of silent sites of rodent genes. Further investigations of selection at synonymous sites will require more reliable estimates of substitution rates.

To date, most studies of mammalian genes have employed approximate methods of estimating substitution rates. Although such studies intended to examine the effect of nucleotide content, their estimation proce-

dures ignored unequal nucleotide frequencies. Most approximate methods also ignored the transition/transversion rate bias. Recent studies suggest that ignoring the transition/transversion rate bias or codon usage bias could lead to systematically biased estimates of substitution rates (Ina 1995; Yang and Nielsen 1998, 2000). A method that accounts for those features of DNA sequence evolution is ML. By employing a codon model of substitution, the ML method also uses probability theory to correct for multiple hits and weight evolutionary pathways between codons (Goldman and Yang 1994; Muse and Gaut 1994).

The objective of this study was to evaluate differences between ML and approximate methods and to evaluate their impacts on hypothesis testing. We compiled a sample of 82 homologous genes from three mammalian orders and estimated the rates of synonymous and nonsynonymous substitution for each gene using the ML method and two popular approximate methods (NEI and Gojobori 1986; Ina 1995). These data were used to evaluate the sensitivity of testing the following two null hypotheses: (i) the rate of synonymous substitution is independent of nucleotide composition, and (ii) the rate of synonymous substitution is independent of the rate of nonsynonymous substitution. ML analysis indicated that synonymous substitution rates were positively correlated with GC content at third codon positions but were independent of the nonsynonymous rate. Approximate methods, however, indicated opposite relationships, i.e., synonymous substitution rates were independent of GC content at third codon positions but were positively correlated with the nonsynonymous rate. The differences were found to be due to the failure of approximate methods to properly account for the transition/transversion rate bias and unequal codon frequencies.

MATERIALS AND METHODS

Sequence data: We analyzed the aligned sequences of 82 nuclear genes from the mammalian orders Artiodactyla, Primates, and Rodentia. The data set is a composite of 49 genes analyzed by Ohta (1995) and 48 genes analyzed by Alvarez-Valin *et al.* (1998). The total number of genes in our analysis is 82 because 7 genes were used by both studies and because 8 genes were excluded due to regions of ambiguous alignment. Small differences between studies in number of codons analyzed are due to removal of initiation codons and minor adjustments to alignments.

Nucleotide composition and synonymous codon usage: G + C content at third codon positions (GC3) and codon usage bias, measured using the effective number of codons (ENC; WRIGHT 1990), were calculated for each gene. ENC ranges from 20 to 61 with a smaller value indicating a greater bias. GC3 and ENC were computed using the program Codon W written by John Penden. Tests of compositional homogeneity among mammalian orders were conducted for each gene using chi-square tests of contingency tables of nucleotide counts.

Estimation of the numbers of synonymous (d_s) and nonsyn-

onymous (d_N) **substitutions per site:** ML analysis was performed using the PAML package (YANG 1999). The models account for transition/transversion rate bias (κ) and codon usage bias (see YANG and NIELSEN 1998 for details). We used two models to determine equilibrium codon frequencies. The first model used the nucleotide frequencies at the three positions of the codon and had $3 \times (4-1) = 9$ parameters. The second model used empirical estimates of 61 codon frequencies and had 60 parameters. Likelihood ratio tests comparing those two models (d.f. = 60 - 9 = 51) were significant for 81 of the 82 genes (data not shown). Analyses of substitution rates using both models were similar and hence only results obtained using empirical estimates of codon frequencies are presented.

Likelihood ratio tests of the assumption that the nonsynony-mous/synonymous rate ratio ($\omega = d_{\rm N}/d_{\rm S}$) is homogeneous for all three mammalian lineages were performed by comparing two models of $d_{\rm N}/d_{\rm S}$ ratios (Yang and Nielsen 1998). Model 0 assumed the same ratio (ω_0) for all three branches of the artiodactyl, primate, and rodent tree, whereas model 1 allowed independent $d_{\rm N}/d_{\rm S}$ ratios ($\omega_{\rm A}$, $\omega_{\rm P}$, $\omega_{\rm R}$) for the three branches. Twice the log-likelihood difference under these two models was compared to a χ^2 distribution with d.f. = 2. This constitutes a likelihood ratio test of the strict neutral hypothesis. Model 1 also was used to obtain lineage-specific estimates of $d_{\rm S}$ and $d_{\rm N}$ for each gene.

Estimates of d_8 and d_N also were computed pairwise between sequences using the approximate methods of Nei and Gojobori (1986) and Ina (1995). The PAML package (Yang 1999) was used to implement the method of Nei and Gojobori (1986) and Ina's program (dists1, available at ftp.nig.ac.jp) was used to implement method 1 of Ina (1995). To facilitate comparison of approximate and ML methods, we also estimated d_8 and d_N in a pairwise fashion between the three orders of mammals using ML (Goldman and Yang 1994).

ML estimation can be performed under different model assumptions. We thus changed the models to investigate the effects of nucleotide (codon) frequencies and transition/transversion rate bias on estimation of d_S and d_N . If one compares a model in which κ is fixed to 1 (the rate of transition is set equal to the rate of transversion) to a model without such a constraint, the difference in d_S and d_N indicates the bias that arises from failure to account for the transition/transversion ratio. Likewise, if one compares a model in which codon frequencies are assumed to be equal (1/61) to a model where codon frequencies are free parameters, the difference in d_S and d_N indicates the bias that arises from failure to account for unequal codon usage.

RESULTS

Nucleotide (codon) usage bias and transition/transversion bias are common features of mammalian DNA sequence evolution: GC content at third codon positions (GC3) varied greatly among genes, ranging from 29 to 96%. Consistent with the suggestion that most mammalian genes are located in GC-rich isochores (Bernard 1993), we observed that the majority of genes (60%) were GC rich (GC3 > 60%) at third codon positions. Only a small proportion of genes (5%) were AT rich (AT3 > 60%) at third codon positions. Mean values of GC3 were 65, 62, and 62% for artiodactyl, primate, and rodent genes, respectively.

Consistent with patterns of nucleotide bias, codon usage also varied greatly among genes, with ENC rang-

ing from small values indicating highly biased codon usage (e.g., primate neurophysin 1=30.8) to large values indicating unbiased codon usage (e.g., rodent transforming growth factor $\beta 1=60.4$). Mean values of ENC were 46.8, 47.6, and 49.6 in artiodactyls, primates, and rodents, respectively. ML estimates of the transition/transversion rate ratio, κ , indicated that a transition bias was also present in all the sampled genes (Table 1). Collectively, these data show that transition/transversion bias and biased nucleotide (codon) frequencies are common features of DNA sequence evolution in mammalian genes.

Lineage-specific estimation of substitution rates by maximum likelihood: Results of ML analyses using model 0 (one $d_{\rm N}/d_{\rm S}$ ratio) and model 1 (lineage-specific $d_{\rm N}/d_{\rm S}$ ratios) are presented in Table 1. Using a likelihood ratio test, homogeneity of $d_{\rm N}/d_{\rm S}$ ratio was rejected for 33 (40%) of the sampled genes (Table 1). Furthermore, there were 6 genes in the primate lineage (CD3 ϵ antigen, growth hormone receptor, insulin-like growth factor 1, interleukin 6 receptor, interleukin 7, osteopontin) and one gene in the artiodactyl lineage (interleukin 2) for which $d_{\rm N}/d_{\rm S}$ ratios were >1.0. Because positive selection could adversely affect our investigation (Makalowski and Boguski 1998), gene and lineage combinations for which the $d_{\rm N}/d_{\rm S}$ ratio was >1 were excluded from further analysis.

Values of $d_{\rm N}$ and $d_{\rm S}$ were estimated separately for the artiodactyl, primate, and rodent lineages using model 1 (Table 1). Estimates of $d_{\rm S}$ for these lineages were positively correlated (artiodactyl vs. primate, $r^2=0.1343$, P=0.0013; artiodactyl vs. rodent, $r^2=0.2993$, P<0.0001; primate vs. rodent, $r^2=0.2632$, P<0.0001). Similarly, estimates of $d_{\rm N}$ were correlated between lineages (artiodactyl vs. primate, $r^2=0.5758$, P<0.0001; artiodactyl vs. rodent, $r^2=0.6401$, P<0.0001; primate vs. rodent, $r^2=0.5763$, P<0.0001). These findings are consistent with previous reports that substitution rates were variable among genes, and genes with higher substitution rates in one lineage tended to have higher rates in other lineages as well (Bulmer et al. 1991; Mouchiroud et al. 1995).

Hypothesis testing using maximum-likelihood estimates of substitution rates: The null hypothesis that the rate of synonymous substitution is independent of nucleotide composition was evaluated by linear regression of lineage-specific estimates of $d_{\rm S}$ and GC3. There was a significant positive correlation between $d_{\rm S}$ and GC3, with $r^2=0.45,\,0.27,\,{\rm and}\,0.26$ in artiodactyls, primates, and rodents, respectively. Because results were similar for all three lineages, only results for artiodactyl genes are presented in Figure 1.

Because nonstationary genes could have negative impacts on analyses of substitution rates (Lanave *et al.* 1984; Saccone *et al.* 1989; Mouchiroud and Gautier 1990), each gene was tested for homogeneity of nucleotide frequencies. Chi-square tests at third positions of

the codon indicated significant heterogeneity among lineages in 27 (33%) of the genes (Table 1). Reanalysis of the subset of genes defined by homogeneity of nucleotide frequencies also yielded a significant positive relationship between $d_{\rm S}$ and GC3 (artiodactyls, $r^2=0.5053$, P<0.0001; primates, $r^2=0.2351$, P=0.0004; rodents, $r^2=0.4225$, P<0.0001). This finding indicated that a positive correlation between $d_{\rm S}$ and GC3 was not a consequence of including genes that were nonstationary for nucleotide frequencies.

The null hypothesis that synonymous and nonsynonymous substitution rates are independent was evaluated by linear regression of lineage-specific estimates of $d_{\rm S}$ and d_N . In the artiodactyl and rodent lineages, the correlation between $d_{\rm S}$ and $d_{\rm N}$ did not differ significantly from zero (Figure 2, a and b). Primate genes, however, exhibited a significant positive correlation between $d_{\rm S}$ and d_N (Figure 2c). This plot has an outlier gene (growth hormone), and Makalowski and Boguski (1998) demonstrated that outliers could have adverse effects on linear regression of $d_{\rm S}$ and $d_{\rm N}$. When growth hormone was removed, the correlation between d_S and d_N did not differ significantly from zero (Figure 2d). Reanalysis of artiodactyl and rodent lineages to the exclusion of other outlier genes had no effect on the inferred relationship between d_S and d_N (data not shown). Given that previous analyses of growth hormone indicated episodes of positive selection (Ohta 1993; Wallis 1996), we excluded it from further analyses.

The null hypothesis that synonymous and nonsynonymous substitution rates are independent was retested by using $d_{\rm S}$ and $d_{\rm N}$ estimated from the subset of genes defined by homogeneous $d_{\rm N}/d_{\rm S}$ ratios. None of the comparisons exhibited a significant correlation (artiodactyls, $r^2=0.0297$, P=0.2367; primates, $r^2=0.0304$, P=0.2413; rodents, $r^2=0.0025$, P=0.7318). Similar results also were obtained from reanalysis of the subset of genes defined by stationary nucleotide frequencies (artiodactyls, $r^2=0.0003$, P=0.9074; primates, $r^2=0.0284$, P=0.2525; rodents, $r^2=0.0013$, P=0.7919). These results indicate that lack of a correlation between $d_{\rm S}$ and $d_{\rm N}$ was not a consequence of including genes with nonstationary nucleotide frequencies or with variable $d_{\rm N}/d_{\rm S}$ ratios among lineages.

Hypothesis testing using approximate estimates of substitution rates: The two null hypotheses were tested using two approximate methods (Nei and Gojobori 1986; Ina 1995). Consistent with some previous analyses that used approximate methods (Miyata *et al.* 1982; Bernardi *et al.* 1993; Matassi *et al.* 1999; Smith and Hurst 1999), the correlation between $d_{\rm S}$ estimated between a pair of lineages and the average GC3 between the same pair of lineages did not differ significantly from zero. Also consistent with previous analyses based on approximate methods (Graur 1985; Li *et al.* 1985; Wolfe and Sharp 1993; Mouchiroud *et al.* 1995; Ohta and Ina 1995; Makalowski and Boguski 1998; Smith

 L_c is the length of a gene in codons, χ^2 is the chi-square value for a contingency test of equal nucleotide frequencies at third codon positions. κ_0 and ω_0 are the transition/transversion rate ratio and nonsynonymous/synonymous rate ratios estimated using model 0. (A), (P), and (R) indicate the artiodactyl, primate, and rodent lineages. ℓ_1 — ℓ_0 is the log-likelihood difference between model 0 and model 1. * $^*P < 0.001$, *** $^*P < 0.001$.

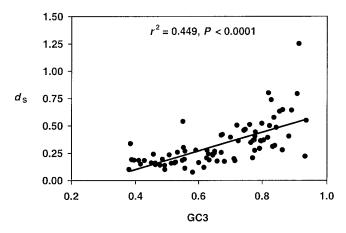

FIGURE 1.—The relationship between ML estimates of d_8 and GC3 in artiodactyl genes.

and Hurst 1999), there was a significant positive correlation between $d_{\rm S}$ and $d_{\rm N}$. Because results were similar for all three comparisons, only comparisons between artiodactyl and primate genes are presented in Figure 3. These findings indicate that approximate and ML methods led to exactly opposite conclusions.

Pairwise estimation of d_s and d_N using maximum likelihood is consistent with lineage-specific estimation of d_s and d_N : Approximate methods are applicable only to pairwise sequence comparisons, whereas ML results discussed above were obtained from joint analysis of all sequences on a phylogeny. To facilitate direct comparison of approximate and ML methods, d_s and d_N were re-estimated in a pairwise fashion between the sampled lineages using ML (GOLDMAN and YANG 1994). In all three pairwise comparisons, estimation of substitution rates via ML yielded results similar to those obtained by using lineage-specific estimates of substitution rates; *i.e.*, a significant positive correlation was observed between

 $d_{\rm S}$ and GC3, and a nonsignificant correlation was observed between $d_{\rm N}$ and $d_{\rm S}$ (Figure 3, c and f). These findings indicate that comparisons could be made between approximate and ML methods by utilizing ML to estimate $d_{\rm N}$ and $d_{\rm S}$ in a pairwise fashion between lineages.

Reconciling differences between methods: We have shown that transition/transversion bias is a common feature of DNA sequence evolution in these genes. The approximate method of Nei and Gojobori (1986) ignores the transition/transversion bias by assuming rate equality. We changed the parameters of the codon model to investigate the effects of this assumption on the estimation of d_S and d_N (see MATERIALS AND METHods). The effect of ignoring the transition/transversion rate bias was consistent underestimation of the numbers of synonymous sites (S; Figure 4a). Because transitions at third codon positions are more likely to be synonymous than transversions, ignoring the transition/transversion bias leads to underestimation of S and overestimation of $d_{\rm S}$ (Li et al. 1985; Pamilo and Bianchi 1993; Ina 1995; YANG and NIELSEN 1998).

We also have shown that biased nucleotide (codon) frequencies were characteristic of the sampled genes. Both the methods of Nei and Gojobori (1986) and Ina (1995) ignore this feature of DNA sequence evolution. We changed the parameters of the codon model to investigate the effect of this assumption on estimation of d_S and d_N (see Materials and Methods). Ignoring codon bias had the opposite effect to ignoring the transition/transversion bias, in that Swas consistently overestimated (Figure 4b). These results indicate that the number of synonymous sites (S) available to mutation was restricted to varying degrees by biased codon usage. Because approximate methods (Nei and Gojobori 1986; Ina 1995) assume unbiased codon usage, counts of the number of synonymous substitutions will be mea-

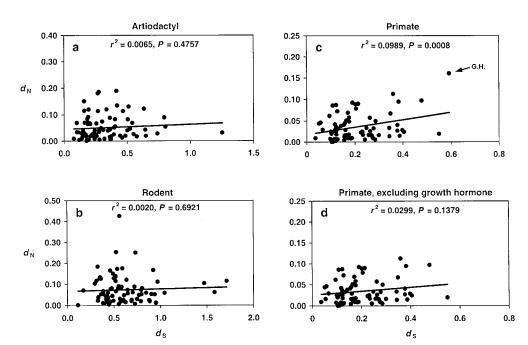

FIGURE 2.—The relationship between ML estimates of d_S and d_N in artiodactyl (a), rodent (b), and primate (c and d), genes. G.H. indicates the growth hormone gene.

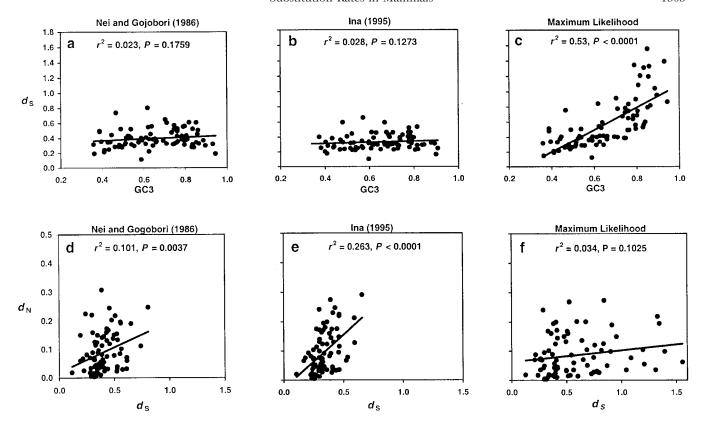

FIGURE 3.—The relationship between pairwise estimates of d_s and mean GC3 (a-c) and the relationship between pairwise estimates of d_s and d_N (d-f). All plots represent a pairwise comparison between artiodactyl and primate genes. Pairwise estimates of substitution rates were computed by using the approximate methods of Nei and Gojobori (1986) and Ina (1995) and also by using ML (Goldman and Yang 1994).

sured against too large a number of synonymous sites, and therefore d_S will be underestimated. Because the total number of sites is fixed in a gene, the bias in estimation of nonsynonymous sites (N) is opposite to that of S.

To understand why different methods produced different results concerning the correlation of d_s with GC3 or d_N , we examined the following two summary statistics: (i) the ratio of the approximate estimate of d_s to the ML estimate of d_S (d_S ratio) and (ii) the ratio of the approximate estimate of d_N to the ML estimate of d_N (d_N ratio). Plots of the d_S ratio and d_N ratio against GC3 illustrate the complexity of the biases involved in approximate estimation of d_S and d_N (Figure 5). For genes with highly biased nucleotide (codon) usage (GC3 > 60%), both approximate methods were consistent with our earlier analysis of codon models that ignored nucleotide (codon) frequencies (Figure 4b) in that d_s was underestimated and d_N was overestimated (Figure 5). However, when nucleotide (codon) bias was weak (GC3 < 60%), the two approximate methods differed in the direction of bias, with the method of NEI and GOJOBORI (1986) overestimating d_s and underestimating d_N (Figure 5a) and the method of INA (1995) underestimating $d_{\rm S}$ and overestimating $d_{\rm N}$ (Figure 5b).

Estimates of d_8 and d_N by the method of NEI and GOJOBORI (1986) were affected differently in genes with

high and low codon bias (Figure 5a) because this method ignores both the transition/transversion rate bias and codon usage bias, and these two features of DNA sequence evolution have opposite effects on estimation of $d_{\rm S}$ and $d_{\rm N}$ (Figure 4). The method of INA (1995) overestimated $d_{\rm S}$ and underestimated $d_{\rm N}$ in genes with both weak as well as strong codon usage bias because this method overcorrects for the transition/transversion rate bias (YANG and NIELSEN 1998), thereby producing bias in the same direction as when codon usage is highly biased. For both methods, codon usage bias had the largest effect on approximate estimation of $d_{\rm S}$ and $d_{\rm N}$ (Figure 5).

To understand the difference between methods concerning the $d_{\rm S}$ and $d_{\rm N}$ correlation, we examined the relationship between $d_{\rm S}$ ratios and ML estimates of $d_{\rm N}$ and the relationship between $d_{\rm N}$ ratios and ML estimates of $d_{\rm S}$. Although approximate methods produced highly biased estimates of $d_{\rm S}$ (Figure 5), there was no significant correlation between this bias ($d_{\rm S}$ ratio) and $d_{\rm N}$ (e.g., artiodactyl vs. primate: NeI and Gojobori 1986, $r^2 = 0.025$, P = 0.1539; INA 1995, $r^2 = 0.017$, P = 0.2505). However, there was a significant positive correlation between the $d_{\rm N}$ ratio and $d_{\rm S}$ (e.g., artiodactyl vs. primate: NeI and Gojobori 1986, $r^2 = 0.227$, P < 0.0001; INA 1995, $r^2 = 0.258$, P < 0.0001). These findings suggest that approximate estimation of $d_{\rm N}$ could interpose a

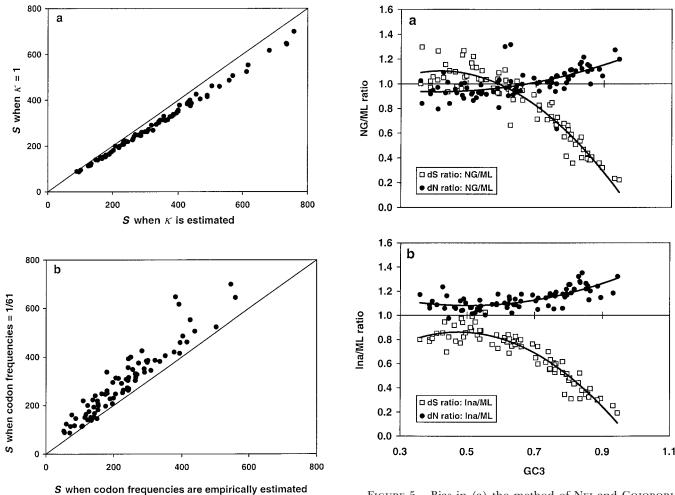

FIGURE 4.—Bias in the estimated number of synonymous sites (S) when (a) transition/transversion ratio (κ) is ignored and (b) when unequal codon frequencies are ignored. Data presented in (a) were estimated using two models with equal codon frequencies (1/61), and in one model κ was a free parameter and in the other model $\kappa=1$ (transition and transversion rates assumed to be equal). Data presented in (b) were estimated using two models with $\kappa=1$, where one model used empirical codon frequencies and the other model assumed equal codon frequencies (1/61).

positive correlation between estimates of nonsynonymous and synonymous substitution rates.

The preceding analyses suggested that failure of the approximate methods to properly account for the transition/transversion rate bias and unequal codon usage has resulted in seriously biased estimates of substitution rates. These biases appear to be the source of conflict between the methods. To test this prediction, we retested the two null hypotheses using substitution rates estimated from a codon model that was modified to ignore biased nucleotide (codon) frequencies and transition/transversion ratio. Linear regression of substitution rates estimated using this codon model yielded results that fit the prediction, *i.e.*, there was no significant correlation between d_8 and GC3 (*e.g.*, artiodactyl

Figure 5.—Bias in (a) the method of Nei and Gojobori (1986) and (b) the method of Ina (1995) as compared to ML. Data represent pairwise comparisons between artiodactyl and primate genes. Bias was measured using the ratio of the approximate estimate of $d_{\rm S}$ to the ML estimate of $d_{\rm S}$ ($d_{\rm S}$ ratio) and the ratio of the approximate estimate of $d_{\rm N}$ to the ML estimate of $d_{\rm N}$ ($d_{\rm N}$ ratio). "NG" indicates the method of Nei and Gojobori (1986), "Ina" indicates method 1 of Ina (1995), and "ML" indicates the maximum-likelihood method of Goldman and Yang (1994).

vs. primate: $r^2 = 0.027$, P = 0.137), and there was a significant positive correlation between d_s and d_N (e.g., artiodactyl vs. primate: $r^2 = 0.124$; P = 0.001).

DISCUSSION

Synonymous substitution rate is positively correlated with nucleotide composition: Mammalian genomes exhibit a degree of structure in the form of long (>300 kb) compositionally homogenous regions of DNA known as isochores (Bernardi 1993). The well-known correlation between GC content at third codon positions of a gene and GC content of the isochore in which that gene resides, permits us to study substitution rates at the level of the isochore (Mouchiroud et al. 1991; Bernardi 1995; Clay et al. 1996). Our results indicate that synony-

mous substitution rates differ among isochores and therefore among different regions of the mammalian genome. Furthermore, the most GC-rich isochores appear to have the highest synonymous substitution rate. These results are significant because arguments against a mutation-based hypothesis for the origin and maintenance of isochores have relied, in part, upon the assumption that synonymous substitution rates do not differ among regions of the mammalian genome (Bernard et al. 1993; Mouchiroud et al. 1995).

The hypothesis that synonymous substitution rates vary among different isochores was originally proposed by Wolfe et al. (1989). Moreover, Wolfe et al. (1989) found remarkably similar rates of silent substitution in six physically linked genes in mouse and rat. Support for the hypothesis of Wolfe et al. (1989) can be found in other studies. MATASSI et al. (1999) investigated synonymous substitution rates among genes lying within one centimorgan of each other in mouse and human. Synonymous substitution rates among these neighboring genes were more similar than among genes that were farther apart on the chromosome (MATASSI et al. 1999). The results of our study, taken together with those of Wolfe et al. (1989) and Matassi et al. (1999), suggest that the perceived gene specificity of synonymous substitution rate reflects, at least in part, regionspecific effects on the rate of synonymous substitution.

MATASSI *et al.* (1999) also investigated GC3 content of genes within one centimorgan of each other and found that the same sets of neighboring genes were more similar to each other in GC content than genes found farther apart on the chromosome. However, in contrast to our study, MATASSI *et al.* (1999) did not find a significant correlation between $d_{\rm S}$ and GC3 and hypothesized that regional similarities in both synonymous substitution rates and nucleotide composition were evolving independently of each other. Values of $d_{\rm S}$ used in their correlation analysis were estimated using the approximate method of LI (1993). Because this method is similar to the method of INA (1995) in that it does not account for biased nucleotide (codon) frequencies, their estimates might be biased.

Our results have important implications for the hypothesis of Alvarez-Valin *et al.* (1998) that selection is acting to enhance translational accuracy in mammals. If selection is acting to enhance translational accuracy, then we should observe a negative correlation between nucleotide (codon) bias and synonymous substitution rate (Akashi 1994). Our finding of a positive correlation between $d_{\rm S}$ and GC3 suggests that synonymous codon usage in mammals is not subject to this type of selective constraint. In support of Akashi (1994), a negative correlation between synonymous substitution rate and codon bias has been observed in Drosophila, bacteria, and yeast (Sharp and Li 1987, 1989; Shields *et al.* 1988; Moriyama and Gojobori 1992; Powell and Mori

YAMA 1997), and in these taxa codon usage also matches tRNA abundance.

The results of this study do not preclude a role for selection in the maintenance of mammalian isochores. It has been suggested that selection might be acting regionally to elevate GC content (BERNARDI et al. 1985, 1988). In this hypothesis, selection acts to elevate GC content in regions of the genomes of warm-blooded vertebrates as a means of protecting DNA from heat degradation (Bernardi et al. 1985, 1988). In support of this hypothesis, Eyre-Walker (1999) reported that patterns of silent site variation in major histocompatibility genes of mammals were not consistent with neutral expectations, but were consistent with the influence of selection on nucleotide composition. However, Fran-CINO and OCHMAN (1999) recently reported that interspecific variation in two globin pseudogenes that reside in different isochores was consistent with the effect of differential GC mutation pressure. Although data presented here are not sufficient to resolve this long-standing controversy, our conclusion that synonymous substitution rates vary among different isochores, taken together with the recent findings of Francino and Och-MAN (1999), suggest at least a partial role for mutation in the maintenance of mammalian isochores.

Synonymous substitution rate is independent of nonsynonymous substitution rate: SMITH and HURST (1999) estimated substitution rates between pairs of rat and mouse genes and found that the correlation between $d_{\rm S}$ and $d_{\rm N}$ obtained from ML was less than neutral expectations (OHTA and INA 1995), whereas the correlation obtained from approximate methods was greater than neutral expectations. In this regard the results of their study are compatible with ours. However, the findings of SMITH and HURST (1999) differ from ours in that a positive correlation between ML estimates of $d_{\rm S}$ and $d_{\rm N}$, although less than neutral expectations, was significant. The reason for this difference is unclear.

A potential source of correlation between $d_{\rm S}$ and $d_{\rm N}$ is variation among loci in codon usage and base frequencies. The significant correlation between $d_{\rm S}$ and $d_{\rm N}$ indicated by the approximate methods, which ignore codon usage bias, disappeared after we corrected for codon usage and base frequencies. Results of simulation studies (Yang and Nielsen 1998, 2000) support the view that the differences among methods observed in the present study may be attributed to biases in estimation.

What is clear from both this study and the study of SMITH and HURST (1999) is the sensitivity of such analyses to the estimation method and to assumptions concerning the transition/transversion rate bias and nonrandom codon usage. Unbiased estimation of substitution rates is a critical aspect of reliably measuring the effectiveness of selection at synonymous sites.
